Retirement saving and asset prices

A two-period model, read one step at a time

Start with behavior

- **Consumption smoothing.** A worker earns while young and has no labor income when retired. They value consumption on both dates, so some current income is carried forward. This is a preference for a smoother path, not a literal fixed retirement spending target.
- **Two separate choices.** The worker chooses how much to save, then how to divide those savings between a risky claim and a safe claim. Changes in returns can move these two choices by different amounts.
- **Both return effects matter.** A higher return makes future consumption cheaper relative to present consumption (substitution). It also makes a given saving plan richer (income). The net change in saving depends on preferences and the initial position.
- **Prices clear claims.** The total date-1 payoffs of existing claims are fixed for the pricing exercise. More demand can therefore raise their date-0 prices and lower the returns earned by new buyers. This is a model of trading existing assets; there is no choice to build new capital.

Three blocks to remember

- **1. Household:** choose current consumption and holdings of the two claims.
- **2. Payoffs:** one claim pays a risky amount; the other pays a safe amount at retirement.
- **3. Clearing:** all claims must be held, so their prices adjust until desired holdings equal the fixed units available.

Primitives

- **Dates and people.** There are dates 0 (working) and 1 (retirement), and $n > 0$ identical workers. Initial owners sell existing claims at date 0 and receive the proceeds. Their choices are outside the model. The claims pay once at date 1 and then expire.
- **Endowments.** Each worker receives $y > 0$ units of date-0 goods and no date-1 labor income. Claim payoffs at date 1 come from exogenous resources; the issuer's production or fiscal budget is outside the model.
- **Preferences.** Each worker maximizes $u(c_0) + \beta E[u(c_1)]$, with $\beta > 0$. For $\gamma > 0$, marginal utility is $u'(c) = c^{-\gamma}$. When $\gamma \neq 1$, $u(c) = \frac{c^{1-\gamma}}{1-\gamma}$; when $\gamma = 1$, $u(c) = \ln c$.
- **Claims.** The stock pays D^L in the low state and D^H in the high state, with probabilities $1 - p$ and p. The safe claim pays $B > 0$ in either state. Both stock payoffs are positive. Their date-0 prices are P_s and P_b.
- **Risky-claim supply.** Exactly one aggregate stock claim exists at every candidate price, a vertical supply schedule: $|Q|_s = 1$. There is no share issuance, repurchase, or investment choice. A shock to D^L or D^H changes the payout **per claim**, not the number of stock claims.
- **Safe-claim supply.** Exactly one aggregate safe claim exists at every candidate price, also a vertical supply schedule: $|Q|_b = 1$. The model has no new bond issuance or collateral creation when the safe price rises or its yield falls. The promise of B in either state is taken as backed by resources outside the model. More issuance would require a specified source of future goods or taxes to pay B on each new claim.
- **Holdings and budgets.** A worker buys q_s stock units and q_b safe units:

$$c_0 + P_s q_s + P_b q_b = y, \quad c_1^j = D^j q_s + B q_b, \quad j \in \{L, H\}.$$

We require $q_s, q_b \geq 0$. Saving is the **worker's date-0 flow** $s = y - c_0 = P_s q_s + P_b q_b$. This is spending on assets, not net saving for the whole economy. Its stock share by market value is $\alpha = P_s \frac{q_s}{s}$.

- **Returns.** The stock's state-dependent gross return is $R_s^j = \frac{D^j}{P_s}$; the safe gross return is $R_b = \frac{B}{P_b}$. Because each claim pays once and expires, these returns have no resale-price term.

The full model

- **Household problem.** Taking P_s and P_b as given, choose c_0, q_s, q_b to maximize utility subject to the two budgets and nonnegative holdings. Equivalently, choose s and α with $c_1^j = sR_p^j$ and $R_p^j = \alpha R_s^j + (1-\alpha)R_b$.
- **Saving condition.** At an interior optimum, the marginal utility lost now equals expected discounted marginal utility gained from the portfolio payoff:

$$c_0^{-\gamma} = \beta E\Big[R_p^j \big(c_1^j\big)^{-\gamma}\Big].$$

- **Portfolio condition.** At an interior stock share, the extra risky payoff must have zero marginal-utility-weighted value:

$$E\Big[(R_s^j - R_b)\big(c_1^j\big)^{-\gamma}\Big] = 0.$$

  If this expression is nonpositive at $\alpha = 0$, hold no stock; if nonnegative at $\alpha = 1$, put all saving in stock.
- **Market clearing.** The fixed supply schedules imply $nq_s = 1$ and $nq_b = 1$. Equivalently, $n\alpha s = P_s$ and $n(1-\alpha)s = P_b$. Each worker holds $\frac{1}{n}$ physical units of **each** claim in every equilibrium; changes in portfolio value shares reflect prices, while demand at old prices can shift. Retirement consumption is $c_1^j = \frac{D^j + B}{n}$.
- **Prices.** Let $c_0 = y - s$. The two asset-pricing conditions become

$$P_s = \beta c_0^\gamma E\Big[D^j \big(c_1^j\big)^{-\gamma}\Big], \quad P_b = \beta c_0^\gamma E\Big[B\big(c_1^j\big)^{-\gamma}\Big].$$

  Together with $ny = nc_0 + P_s + P_b$, these determine consumption, saving, portfolio shares and prices.
- **A one-equation solution.** Substitute $c_1^j = \frac{D^j + B}{n}$ into the sum of the two price equations. The unique positive solution for c_0 satisfies

$$y = c_0 + \beta n^{\gamma-1} c_0^\gamma E\Big[\big(D^j + B\big)^{1-\gamma}\Big].$$

  The code solves this monotone equation, then computes the two prices separately. This is the complete two-period market-clearing model used in the market-clearing figures.
- **What the supply assumption does.** The safe-supply line in Graph 6 is vertical. When weaker stock payouts raise desired safe holdings at the old prices, no new safe units appear; P_b rises and $R_b = \frac{B}{P_b}$ falls. With an upward-sloping safe supply schedule, some demand could instead produce new claims, so the price and return changes could be smaller. The same issue applies to stock issuance. Modeling either response requires an issuer and the resources backing its new claims.

Illustrative values used below

- **Common behavior:** $y = 1$, $\beta = 0.60$, $\gamma = 5$. These describe one stylized model period; the rates below are not annual estimates.
- **Full-model payoffs:** $D^L = 0.17$, $D^H = 0.23$, $p = 0.5$, $B = 0.30$, and initially $n = 1$.
- **Baseline solution:** $\frac{s}{y} = 45.9\%$, $P_s = 0.179$, $P_b = 0.281$, and the stock receives 38.9% of saving. The expected stock gross return is 1.118 and the safe gross return is 1.069.

Reproduce the figures

- **Code.** From the repository root run `uv run python blogs/demand_for_investment_is_inelastic/src/two_period_model.py` . It writes nine figures to `figures/` and selected values to `data/two_period_summary.json`.
- **PDF.** From this post directory run `typst compile --root . notes/two_period_model.typ notes/two_period_model.pdf` .

Graph 1: a higher safe return

- **First take the return as given from the worker's point of view.** With a single safe asset paying gross return R, the budget line is $c_1 = R(y - c_0)$. Comparing a higher R rotates it around the income endowment $(y, 0)$.
- **A to H: substitution.** The dotted compensated line is parallel to the new budget line and tangent to the original indifference curve. Current consumption falls from 0.539 to 0.530. If current income were held at its original level, this lower c_0 would mean more saving.
- **H to B: income.** On the actual new budget line, the worker can afford more consumption on both dates. Current consumption rises to 0.577. This income effect is larger than the substitution effect, so saving falls from 0.461 to 0.423 when R rises from 1.07 to 1.30.
- **The point of compensation.** At H, the hypothetical income endowment has been reduced to 0.918. The arrows decompose the change in c_0; H is not a second saving outcome at the original income.

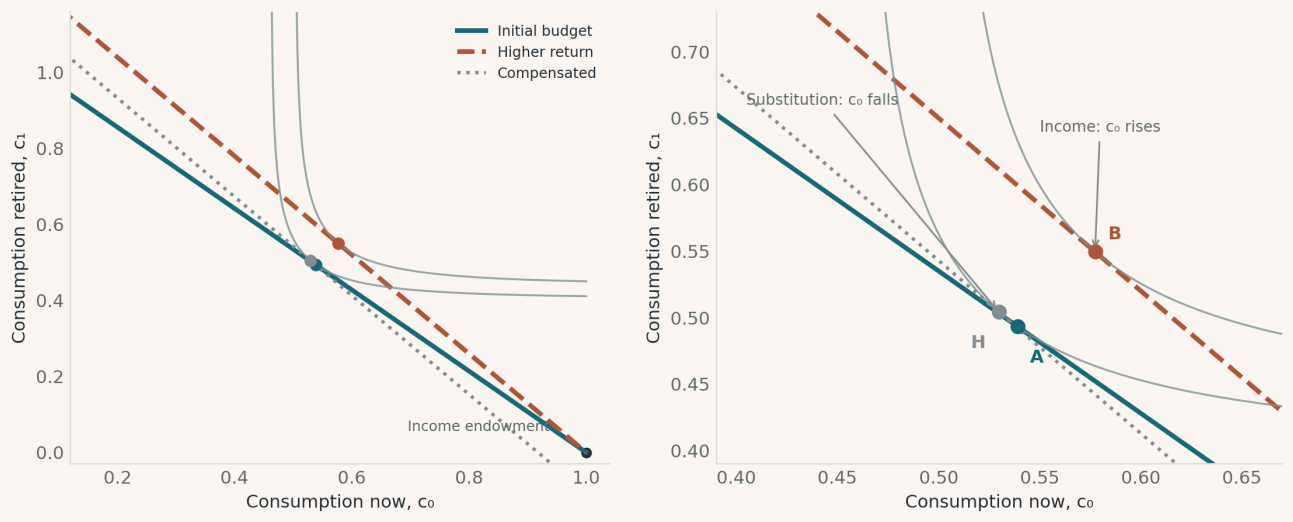

Figure 1: Model illustration. Left: the full budget-line rotation. Right: a close view of the initial choice A, compensated choice H, and new choice B. The larger return change is used so the three points can be seen.

Graph 2: preferences decide the sign

- **Exact safe-asset solution.** Let $a(R) = \beta^{\frac{1}{\gamma}} R^{\frac{1}{\gamma}-1}$. Then

$$\frac{s}{y} = \frac{a(R)}{1 + a(R)}, \quad \frac{d \ln\left(\frac{s}{y}\right)}{d \ln R} = \left(1 - \frac{s}{y}\right)\left(\frac{1}{\gamma} - 1\right).$$

- **Three cases.** For $\gamma < 1$, substitution dominates and saving rises with R. For $\gamma = 1$, the two effects cancel exactly and $\frac{s}{y} = \frac{\beta}{1+\beta}$. For $\gamma > 1$, income dominates and saving falls with R.
- **What this does and does not show.** A small change in the **saving rate** over a given return range can be useful to report, but retirement itself does not make saving fixed. The sign and elasticity follow from γ in this benchmark.

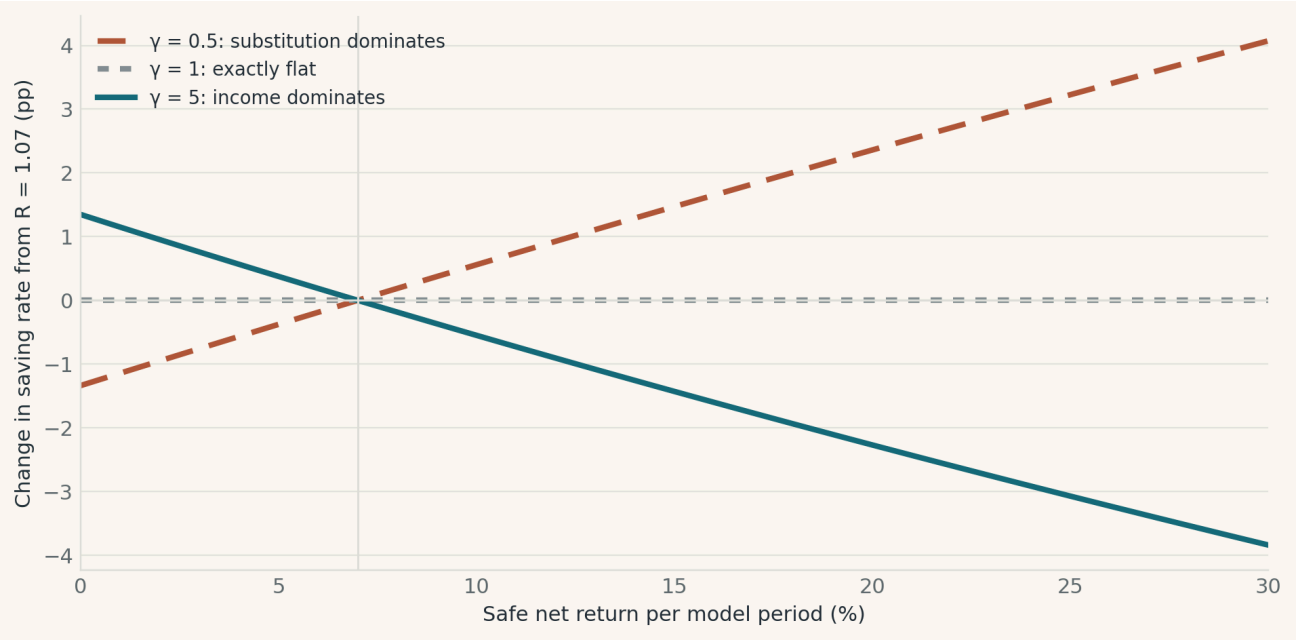

Figure 2: Model result. Each line shows the change in saving divided by income relative to $R = 1.07$, with $y = 1$ and $\beta = 0.60$. The vertical axis is in percentage points.

Graph 3: a better stock return

- **Now hold the safe return at 1.07.** In this partial-equilibrium exercise, the stock pays a gross return of $\mu - \sigma$ or $\mu + \sigma$ with equal probability. Move μ while holding the absolute two-state spread σ fixed.
- **Portfolio margin.** A higher μ raises the stock share α. At $\mu = 1.12$, the share is 44.1% when $\sigma = 0.16$. Raising risk to $\sigma = 0.22$ lowers that share to 22.7%.
- **Saving margin.** With $\sigma = 0.16$, saving changes from 46.1% to about 45.4% of earnings as μ moves from 1.07 to 1.16. This comparison holds R_b fixed. It is not a general theorem that saving always moves less than the stock share.
- **Important boundary.** At $\mu = R_b$ the stock share is zero. Other model-period return ranges or preferences can give a different comparison. In this figure μ is offered to the worker; it is not being set by market clearing.

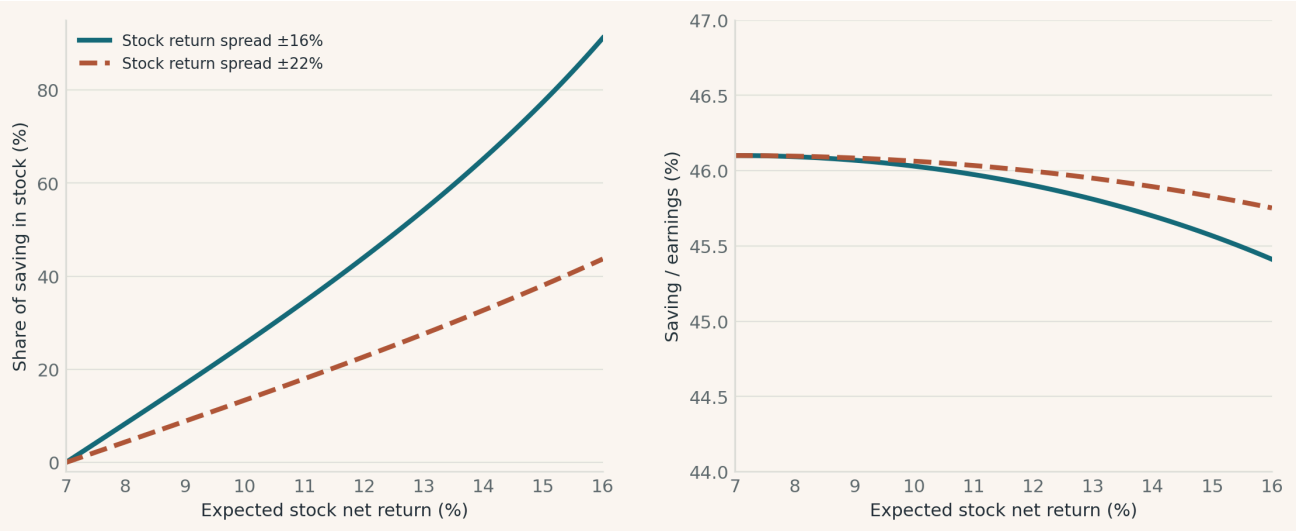

Figure 3: Model result. Expected stock return varies with the safe return fixed at 7% per model period. Solid and dashed lines have different two-state stock-return spreads. The right panel uses a close vertical scale.

Graph 4: more buyers, same total payoff

- **Return to full market clearing.** Fix the total stock payoff D^j and safe payoff B. More identical workers now bid for the same one unit of each claim. This is a buyer-cohort shock, not new saving appearing from outside the model.
- **One-bundle view.** Treat one stock unit plus one safe unit as a bundle with payoff $T^j = D^j + B$ and total price $P = P_s + P_b$. At a candidate price P, desired saving and aggregate demand are

$$a(P) = \left[\beta E\left[\left(\frac{T^j}{P}\right)^{1-\gamma}\right]\right]^{\frac{1}{\gamma}},$$

$$s_{d(P)} = y\frac{a(P)}{1+a(P)}, \quad Q_{d(P;n)} = n\frac{s_{d(P)}}{P}.$$

- **Graphical clearing.** Supply is one bundle. A larger n shifts the demand curve right. The intersection moves up in price. The relative stock/bond price within the bundle is held at its optimal equilibrium ratio while drawing these curves; homothetic preferences keep that ratio unchanged under this cohort shock.

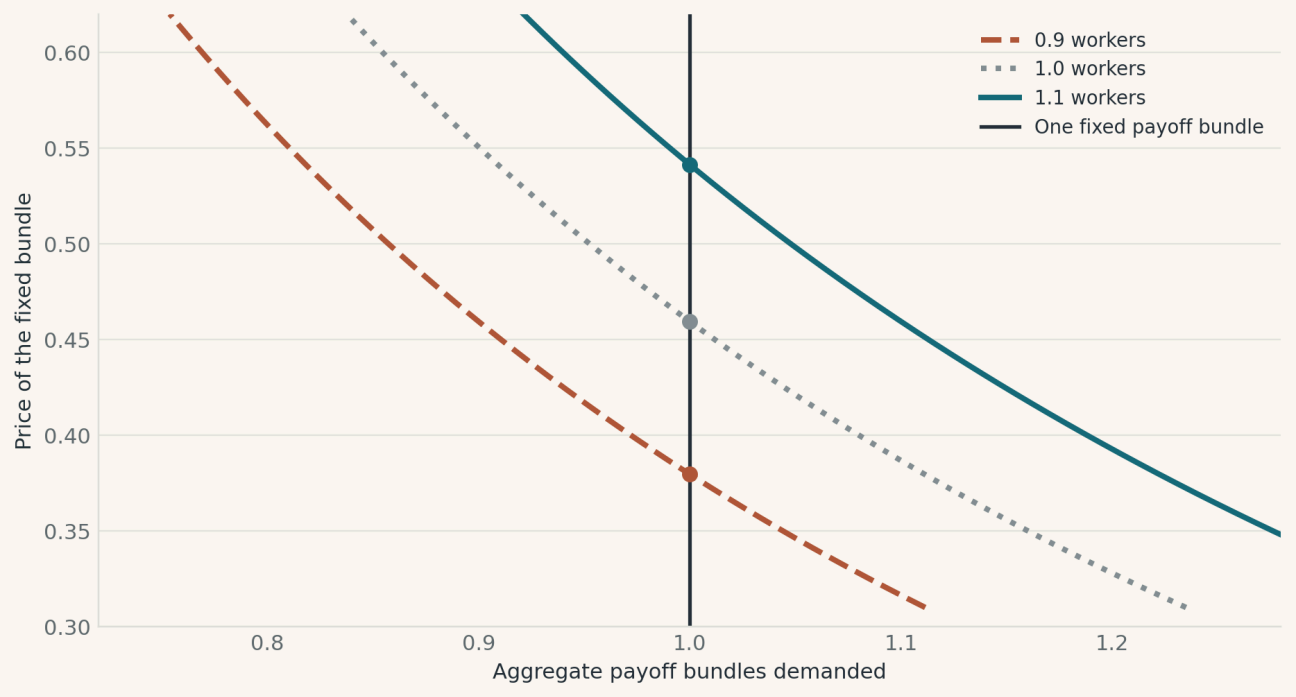

Figure 4: Model result. Each dot is the full-model equilibrium for a different mass of workers. The supply of the existing payoff bundle is fixed at one.

Graph 5: trace both asset prices and returns

- **Prices.** Moving from $n = 0.9$ to $n = 1.1$ raises the stock price from 0.148 to 0.211 and the safe-claim price from 0.232 to 0.331. More workers buy the same total future cash flows.
- **Returns.** Because total payoffs have not changed, the expected stock gross return falls from 1.353 to 0.949 and the safe gross return from 1.294 to 0.907. A gross return below one is possible in this one-period asset market when claims become expensive relative to their terminal payoffs.
- **Worker saving also responds.** Saving per worker rises from 0.422 to 0.492 across that same shock. Total saving by the worker cohort rises from 0.380 to 0.541, exactly matching the value of the claims at each equilibrium. Asset sellers receive this spending, so it is not net saving for the whole economy. The model does not hold worker saving fixed by assumption.
- **Composition.** The stock value share stays at 38.9% under this particular shock because all workers have the same homothetic preferences and both claims' aggregate payoffs remain fixed. That invariance would not generally survive different preferences, existing wealth, or payoff changes.

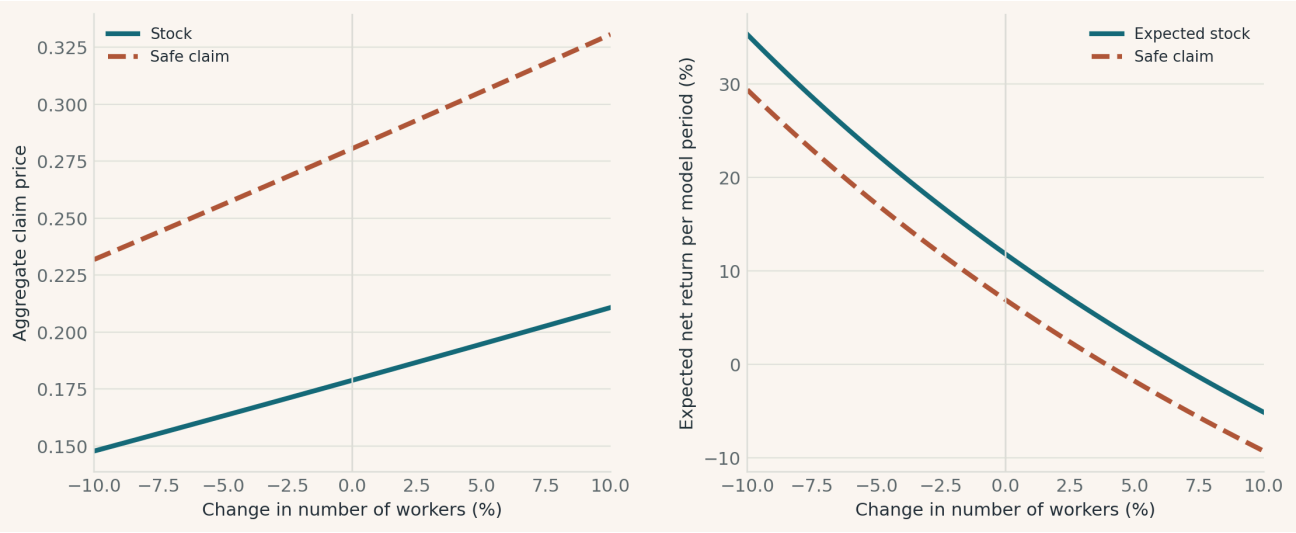

Figure 5: Model result. The horizontal axis varies the number of identical workers relative to the baseline. Both asset prices rise and both expected net returns fall; the two panels use different vertical units.

What the model establishes, and what it leaves open

- **It establishes a conditional saving response.** A retirement motive creates demand for future consumption. The return elasticity of saving still depends on preferences, risk, and the shock under study. The safe-asset benchmark supplies an exact counterexample to a claim that saving must be fixed.
- **It establishes a pricing channel.** More buyers for a fixed stream of payoffs raise existing-claim prices in this two-period economy. The full model solves both saving and portfolio choice; it does not assume a constant aggregate saving pool.
- **It does not establish a real-investment result.** No firm chooses new capital, issues new claims, or changes future output in response to price. To make a claim about investment quantity, add a firm that can produce new capital at a specified marginal or adjustment cost and clear the market for **new** claims separately from trading old ones.
- **It does not reproduce a stock-market flow multiplier or a conventional P/E ratio.** A terminal claim has $\frac{E[D]}{P_s}$ as its expected gross return. A perpetuity with resale has a different return equation. Dollar flows, market capitalization, and payout multiples need separate definitions before comparing them with empirical estimates.

The question: what if the expected stock return falls?

- **Specify the cause.** In this model $\mu = \frac{E[D]}{P_s}$ is the expected **gross** stock return. A lower μ can come from weaker future payouts or from a higher price paid for unchanged payouts. Those shocks need not change consumption or saving in the same way. The Gordon perpetuity analogy adds resale value; here the stock is a terminal claim.
- **The experiment here.** Reduce both stock payouts by 10%: $(D^L, D^H) = (0.17, 0.23)$ becomes $(0.153, 0.207)$. Keep current earnings, the safe payoff, preferences and the number of workers fixed. Re-solve **both** asset markets. Expected stock payout falls from 0.20 to 0.18; the stock price adjusts from 0.179 to 0.173. Thus its expected **net** return falls from 11.8% to 4.2% per model period.
- **Demand for safety and the safe price.** At the old prices, the weaker stock payoff raises desired safe holdings. With one unit of each claim available, the final physical holdings remain $\frac{1}{n}$ per worker; prices adjust instead. The stock receives a smaller share of asset spending (38.9% to 36.5%). The safe price rises from 0.281 to 0.300, so its net return falls from 6.9% to about -0.1%. This yield response is conditional on fixed safe supply.
- **Saving and consumption.** Stock spending falls from 0.179 to 0.173, while safe-claim spending rises from 0.281 to 0.300. Total worker saving rises from 0.459 to 0.473, or by 1.38 percentage points of unchanged earnings. Current consumption falls from 0.541 to 0.527. Expected retirement consumption falls from 0.500 to 0.480 because total future payouts are lower. Workers cut current consumption and bid more for the existing claims; higher asset spending does not create more future goods. Substitution away from lower-return future consumption works against the saving response.
- **An exact saving sign.** Write $T^j = D^j + B$. The full-model equation contains $E\left[\left(T^j\right)^{1-\gamma}\right]$. When every T^j falls, this expectation rises if $\gamma > 1$, so its unique solution has lower c_0 and higher $s = y - c_0$. At $\gamma = 1$ saving is unchanged; for $\gamma < 1$ it falls. Here $\frac{1}{\gamma}$ is the elasticity of intertemporal substitution. Consumption smoothing alone does not fix the saving sign.
- **Limits to the conjecture.** A fall in μ alone does not imply that both dates' consumption fall or that workers rotate into safe claims. If only β rises from 0.60 to 0.75, stock return falls from 11.8% to 7.3% and safe return from 6.9% to 2.6%. Saving rises from 0.459 to 0.479, yet expected retirement consumption stays at 0.500 and the stock spending share stays at 38.9%. Future payoffs did not change.

Graph 6: demand for the two claims

- **Read the stock panel.** Each point offers a candidate stock return μ by setting $P_s = \frac{E[D]}{\mu}$, then lets the safe price move until the safe market clears. The horizontal coordinate is the resulting number of stock claims workers would buy. The vertical black line is the one claim actually available. Only each colored intersection with that line clears **both** markets. The teal and rust curves hold different stock payout streams fixed, so they are two conditional demand schedules, not a path of equilibria.
- **Why show the dotted curve?** It repeats the initial stock payout schedule while holding the safe return at its initial value. Allowing the safe price to respond makes the stock-demand schedule much steeper in return-versus-quantity space. The safe panel shows its own demand at the two stock-return scenarios: lower stock return shifts demand for the safe claim toward a higher price at the one-unit supply.
- **Read the horizontal units carefully.** At the same offered μ, a claim with 10% less payout also costs 10% less. Its **number of units** demanded can therefore be larger, even though the stock spending share is smaller at the new equilibrium. The two dots and the spending comparison below show the combined equilibrium response; a horizontal shift of physical-unit demand alone does not isolate portfolio substitution.

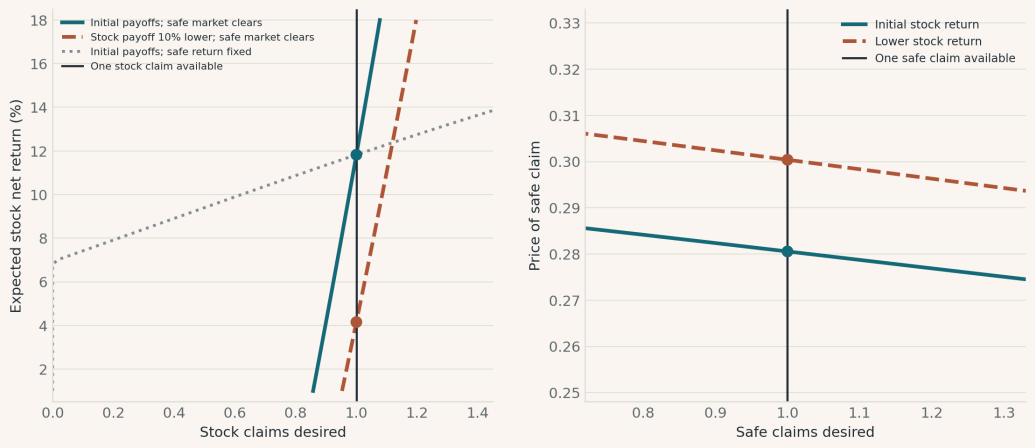

Figure 6: Conditional demand for risky and safe claims. Both black supply lines are one physical claim. The colored dots are the two full equilibria. Stock demand is traced against its expected net return; safe demand is traced against its price.

Graph 7: spending and consumption in the two equilibria

- **Where the extra saving goes.** The rise in safe-claim purchases more than offsets the fall in stock purchases. With one claim of each type, their purchase values are also their equilibrium prices. The right panel shows both consumption dates falling; its points compare levels without using a truncated bar axis.

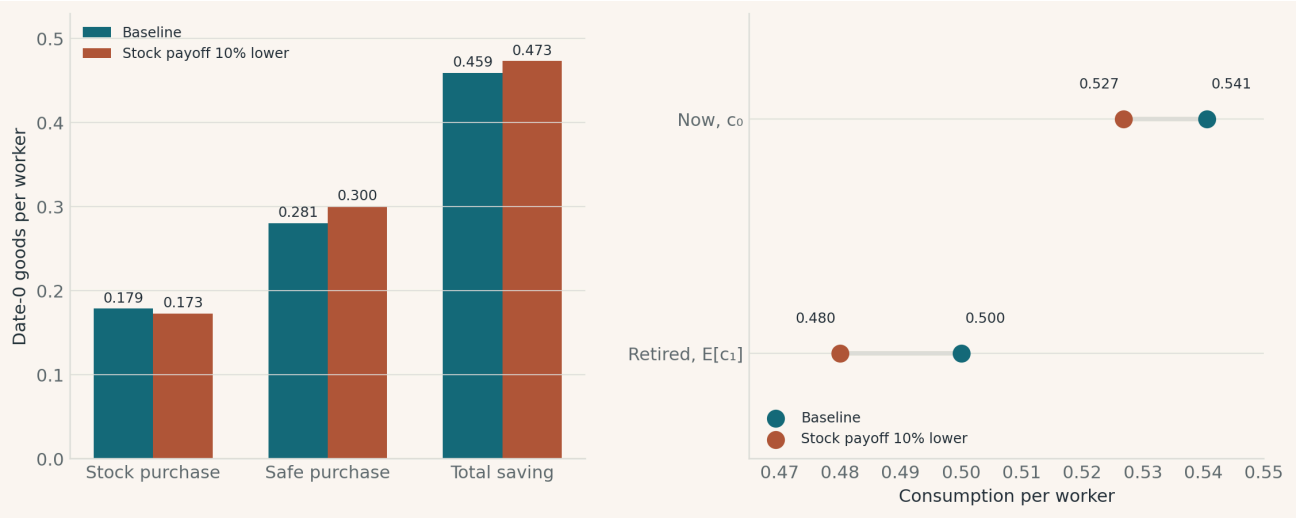

Figure 7: Model result for a 10% cut in both stock payouts. Left: worker spending on each claim and total date-0 saving. Right: current and expected retirement consumption per worker.

Is risky-asset demand inelastic?

- **Define the elasticity first.** For one fixed stock payout stream, measure the local response of desired **physical stock units** to their own price near the initial equilibrium: $\varepsilon_{q_s,P_s} = d\ln\frac{q_s}{d}\ln P_s$. A price increase means a lower offered $\mu = \frac{E[D]}{P_s}$. The dotted schedule in Graph 6, with the safe return held fixed, gives $\varepsilon \approx -23.8$; the teal schedule, with the safe market clearing at each candidate stock price, gives $\varepsilon \approx -1.42$.
- **Interpretation.** With the safe market clearing, a 1% higher stock price reduces desired units by about 1.42% locally. Demand is much less responsive than with a fixed safe return, but lies just above the usual inelasticity cutoff. A payout cut shifts this demand curve, so the two equilibrium dots cannot measure its elasticity.

What kind of model is this?

- **The story in plain language.** Workers earn now and buy claims on future goods: one has a risky payout, the other a fixed payout. The claims already exist. More desire to hold them changes their prices; it does not create new claims or future goods.
- **Why "Lucas tree style"?** Lucas (1978) prices shares in exogenous output. Our risky claim works similarly, but pays only once. The safe claim has an externally backed positive supply. This is a two-period teaching version, not Lucas's continuing economy.
- **Why does saving rise here?** Lower stock payouts reduce retirement resources. With $\gamma = 5$, workers spend more of today's income bidding for the remaining claims; current consumption falls, while future aggregate goods still fall. For this shock, saving rises when $\gamma > 1$. That is a standard income-versus-substitution result under these preferences, not a named theorem about stock demand.
- **Where does safe-asset scarcity enter?** Weaker stock payouts raise the desire to hold the one safe claim. Its price rises and its yield falls. Caballero, Farhi, and Gourinchas study the wider question of who supplies safe assets; this model leaves issuers outside.
- **How does this relate to the inelastic-markets hypothesis?** Gabaix and Koijen study how investor flows move equity prices when institutions change their holdings only a little. Our model shows another kind of weak price response: a 10% fall in stock payouts lowers the stock price only 3.4%, while the safe-claim price rises 7.1%. The stock-demand elasticity of -1.42 measures desired units along one fixed-payout demand curve; it is close to, but above, the usual inelasticity cutoff. The small price response across payout shocks is real in this model, but does not test their flow mechanism.
- **Name to use.** "Two-period exchange asset-pricing model with CRRA preferences and fixed claim supplies" is accurate. "Lucas tree style" is shorthand for its risky claim, not a name for the whole construction.

Graph 8: put the asset prices on the axes

- **Read both panels the same way.** Price is vertical, claims desired horizontal, and the black line is one claim supplied. At each candidate stock price the safe market clears; at each candidate safe price the stock market clears. Only each colored dot clears **both** markets. The panels use different price scales.
- **The payout shock moves demand.** Stock price falls from 0.179 to 0.173; safe price rises from 0.281 to 0.300. Final physical holdings stay at one claim per market. Because the stock payout changes, the line joining the dots is **not** a demand curve or an elasticity estimate. The local stock-demand elasticity -1.42 is measured along the initial stock curve, holding its payout fixed.

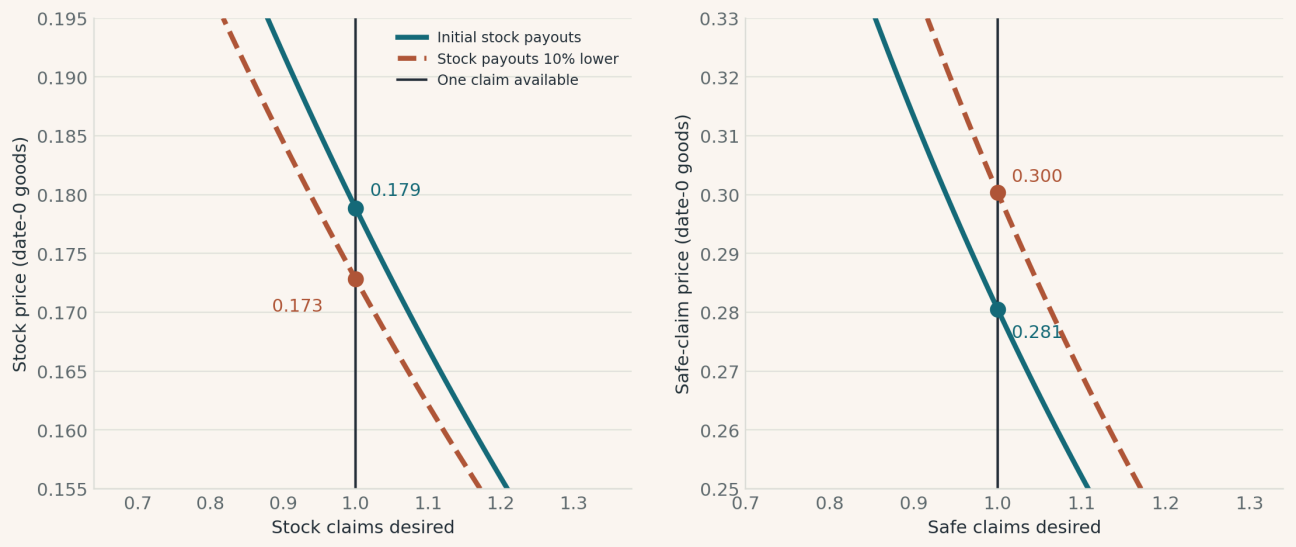

Figure 8: Model-implied conditional demand, with both prices visible. Teal is the initial stock payout stream; rust is the stream after a 10% cut. Each black vertical line marks one claim available. Prices are in date-0 goods per claim; panel scales differ.

Graph 9: prices across a range of stock returns

- **Make the horizontal axis an outcome.** Scale both stock payouts from 85% to 105% of baseline and re-solve both markets at each value. The horizontal axis reports the resulting expected stock **net** return, $\mu - 1$; it is not set independently. The marked dots are the baseline and the 10% payout cut. The two price panels again have different vertical scales.
- **Why the stock price and its return can both fall.** Along this payout path, moving from the baseline to the lower-payout dot cuts expected stock cash flow from 0.20 to 0.18, stock price from 0.179 to 0.173, and expected net return from 11.8% to 4.2%. Cash flow falls faster than price. The grey dotted line holds expected cash flow at 0.20 and merely applies $P_s = \frac{0.20}{\mu}$: at a lower μ, **that** price rises. It is an accounting reference, not another equilibrium path.
- **Read the price changes directly.** The dashed horizontal guides take each equilibrium price to its vertical axis. A 10% payout cut lowers the stock price by just 3.4% and raises the safe price by 7.1%: the stock price falls only about one-third as much as its payout. The expected **net** stock return falls about 65% relative to its initial value, but that percentage uses a small net-return denominator; in percentage-point terms it falls 7.7 points. Neither number is the own-price elasticity of stock demand, because the payout stream and the safe price both change between dots.
- **Safe-claim response.** Along the same full-equilibrium payout sweep, a lower expected stock return comes with a higher safe-claim price and a lower safe return. The association follows from this particular payout shock and fixed safe supply, not from μ alone.

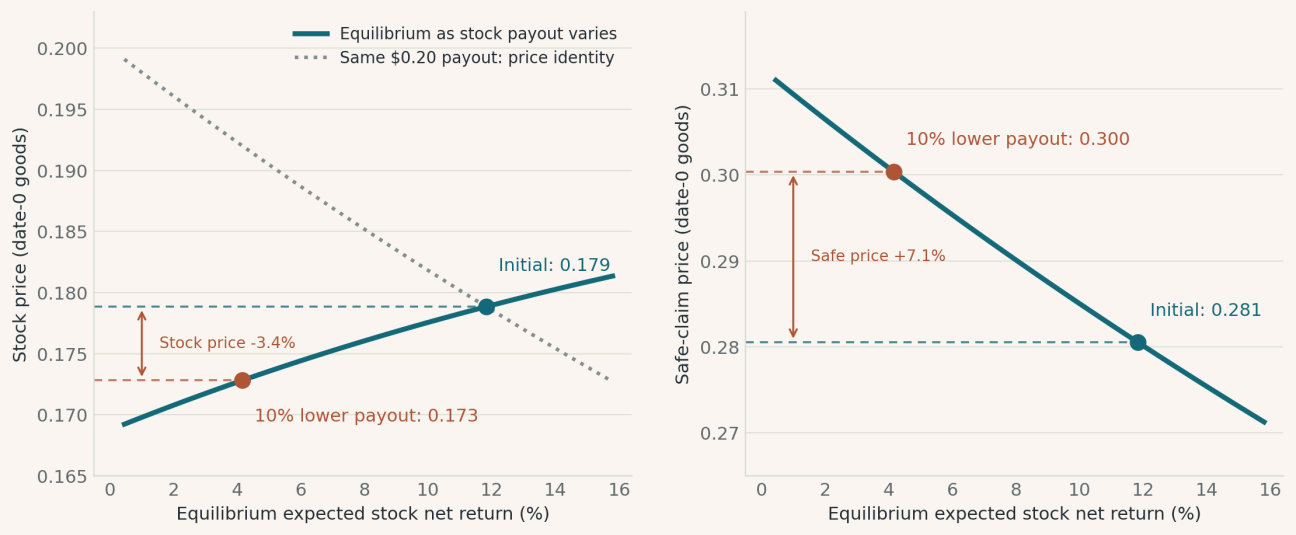

Figure 9: Full-model equilibria as the scale of stock payouts varies. Each point on the solid lines clears both markets. The dotted stock-price line holds expected payout fixed at 0.20 and is only the identity $P_s = \frac{0.20}{\mu}$.
